Effect of size and surrounding forest vegetation on chemical properties of soil in forest gaps

Mehmet Özcan(1), Ferhat Gökbulak(2)

Forest gaps have different climatic conditions as compared to the surrounding areas, depending on gap size and surrounding forest types and affecting the biological, chemical, physical, and hydrological processes in the forest openings. The objective of this study was to determine the effect of forest gap size and surrounding forest cover type (beech or mixed stands) on the soil of forest opening by analyzing several soil chemical properties (pH, electrical conductivity - EC, organic matter - OM, and nutrient content). The study was conducted in the Yuvacik watershed in Izmit (Turkey) and a total of 31 forest gaps of different size (1.44-37.33 ha) and elevations (848-1169 m a.s.l.) were studied. Gaps were divided into three groups with size 0-5 ha, 5-15 ha, and >15 ha. Results showed that forest gap size significantly affected all the investigated chemical properties of the soil, except for soil pH. As gap size increased, sodium (Na) concentration in the soil decreased from 22.72 to 19.57 mg L⁻¹ while potassium (K) and magnesium (Mg) concentrations increased from 83.88 to 134.62 mg L⁻¹ and from 59.46 to 123.96 mg L⁻¹, respectively. Medium-sized gap soils had the lowest OM content, as well as the lowest calcium (Ca) and nitrogen (N) concentrations. Surrounding forest types significantly influenced soil chemical properties in the openings, except for EC, N, and phosphorus (P-Po₄³⁻). Soils in the gaps surrounded by mixed forest had significantly lower pH but higher OM content, K, Na, Ca, and Mg concentrations than soils in beech forest gaps.

Keywords: Forest Openings, Forest Ranges, Plant Nutrients, Soil Chemistry, Forest Soils

Introduction

Forest openings are special habitats differing from the surrounding forest environment and having a significant effect on forest vegetation in various ways. Some of these effects are related to the larger-scale changes in the environment, such as changes in climate, whereas others are due to smaller-scale processes, such as changes in microclimate and light availability. The size of a forest gap can also have a significant effect on the biological processes occurring in the gaps. Forest openings have different microclimatic conditions as compared to the surrounding forest, which can affect the distribution and abundance of plant species and soil chemical properties. As gap size increases, the moisture content and temperature of the soil increase, and the decomposition processes also increase. The surrounding forest cover also plays a role in the distribution of soil nutrients, since the size of the forest gap has an effect on physical and chemical properties of the soil and on the substrate availability. Chunya & Xiuhai (2007) found a positive correlation between gap size and both soil bulk density and total N content, while negative relations were found between gap size and water content, OM in litter, and soil NH₄⁺. Muscolo et al. (2007) reported that C (%), P (%), and OM contents in the soil decreased significantly as gap size increased. In contrast, Thiel & Perakis (2009) studied extractable NH₄⁺ and NO₃⁻ pools, net N mineralization and nitrification rates, and NH₄⁺ and NO₃⁻ ion exchange resin (IER) concentrations in the gaps, finding no significant differences between 0.4 and 0.1 ha gaps for most of the studied parameters. Besides gap size, the surrounding forest cover also plays a significant role in the productivity of forest openings by influencing nutrient dynamics in the soils. Chunya & Xiuhai (2007) found that soil OM content, total N⁻¹ and total K⁺ were greater in the forest gaps than under a Pinus koraiensis canopy. Rhoades et al. (2004) examined the soil properties of forest openings and surrounding forests in Kentucky’s Knobs region and reported that soil pH, extractable cations, bulk density, and soil content were higher and extractable P was lower in the openings compared to the forest soils.

A number of studies have been conducted in forest openings to determine the effect of gap size and the surrounding forest cover on soil chemical properties and nutrient dynamics (Frost & Edinger 1991, Rhoades et al. 2004, Rezaei & Gilkes 2005, Scharenbroch & Bockheim 2007), though the results are not always consistent with each other (Gökbulak & Özcan 2008). In fact, different tree species in the surrounding canopy have been reported to differently affect the soil chemical characteristics in the gaps (Augusto et al. 1998, Hagen-Thorn et al. 2004, Sariyildiz et al. 2005, Wang & Wang 2007, Vesterdal et al. 2008, Kooch et al. 2012). Moreover, gap size of the openings analyzed may have determined differences among the results of the aforementioned studies. Furthermore, harvesting practices carried out in the gaps may be...
Experimental design and analysis

The experiment was arranged in a two-way factorial, completely randomized block design with sub sampling. Factors were gap size (3 levels: 0-5 ha, 5-15 ha, and >15 ha) and surrounding stand type (2 levels: beech and mixed forest trees including beech and oak trees). Analysis of variance (ANOVA) was carried out, and differences among means were verified by the Tukey’s test ($\alpha = 0.05$). In order to meet the assumption of normality and homoscedasticity among treatments, arcsine transformation was applied on percentage data and square root transformation on numerical values, whenever necessary (Zar 1996).

Results

Mean pH values averaged over the surrounding forest stand types were 5.93, 5.80, and 5.96 for gaps with sizes 0-5 ha, 5-15 ha, and >15 ha, respectively, with no significant differences after ANOVA ($P = 0.184$). Contrastingly, surrounding forest vegetation types affected soil pH significantly ($P = 0.044$), with mean values of 5.93 and 5.87 for gaps surrounded with beech and mixed forests, respectively. Significant interaction was found between gap size and the surrounding forest type for soil pH ($P < 0.001$ - Fig. 2a). Moreover, differences in mean pH values between beech and mixed stands were significant in gaps larger than 5 ha after Tukey’s test (Fig. 2a).

Soil EC values were significantly affected by the size of forest openings ($P < 0.001$), with mean values of 209, 163, and 154 $\mu$hos cm$^{-1}$ for the gaps of 0-5 ha, 5-15 ha, and >15 ha, respectively. Soils of the latter two transects were established and five soil samples taken for each. A total of 120 soil samples were collected from the 0-5 ha gaps, 90 samples from the 5-15 ha gaps and 70 samples from the >15 ha gaps.

Samples were air-dried, sieved through a 2 mm mesh, and analyzed for EC and pH (soil/water ratio of 1/5) using a WTW Multi-line P4 universal meter, and total Na$^+$, K$^+$, Ca$^{2+}$, and Mg$^{2+}$ were extracted from soil samples using 1 N ammonium acetate solution and measured using a Shimadzu 1 6601-F (6600) model atomic absorption equipment (APHA-AWWA-WPCF 1975). Extractable P-P$O_4^{3-}$ was determined according to the molibdophosphoric blue color method using a Beckman DU 530 model UV spectrophotometer at 660 nm wavelength as milligram per liter (Ministry of Forestry 1994). In order to estimate soil OM content, soil organic carbon was measured using the Walkley and Black method, and multiplied by a conversion factor of 1.72 (Jackson 1958, SeraIEG-6*1995, Muscolo et al. 2007).

Fig. 1 - Location of the study site.

an additional confounding factor. Indeed, some studies conducted into artificial forest openings (Ritter 2005, Muscolo et al. 2007, 2010) have demonstrated that the soil compaction due to harvesting activities (e.g., logging machines) may affect the hydrological, physical and chemical properties of the soil, as well as the decomposition and mineralization processes, determining an increase in the surface runoff and nutrient leaching, poor aeration, and low moisture capacity and porosity in the soil (Muscolo et al. 2010). Finally, Bartsch (2000) and Scharenbroch & Bockheim (2007) found that gaps had less locations as compared to the surrounding forest stands due to nutrient leaching.

Limited studies are available in Turkey on soil and herbaceous vegetation characteristics in forest openings (Uluocak 1974, Tekeli & Mengül 1991, Alan & Ekiz 2001, Bilgili 2007, Babalık 2008). In this context, the objective of this study was to determine the effect of gap size and the vegetation type in the surrounding forest on selected chemical soil properties ($pH$, $EC$, OM content, and Na$, K^+$, Ca$^{2+}$, Mg$^{2+}$, N$^{3-}$, P-P$O_4^{3-}$ concentration) in a broadleaved mixed forest ecosystem.

Material and methods

Study site

The study site was located in the Yuvacik watershed in İzmit, Turkey (40° 32'-40° 41' N and 29° 29'-30° 08' E - Fig. 1). The site has a humid, moderate temperature and oceanic climate with no summer water deficit, according to the Thornwaite classification system (Ozyuvaci 1999). The average annual precipitation is 1038.7 mm, mostly concentrated between October and March. The average annual temperature is 9.5 °C. The warmest month is July with a mean temperature of 18.7 °C, and the coldest is January with a mean temperature of 0.4 °C. Soils developed mainly from marble, limestone, and schist parent materials.

The study was conducted between 2005 and 2006 and included 31 forest openings, ranging between 848 and 1160 m a.s.l. in elevation and between 1.44 to 37.73 ha in size (Özcan 2010). All forest openings were located on a flat terrain and were surrounded by beech stands or a mixture stand of different forest trees including beech and oaks.

Sample collection and analyses

Forest openings were selected and positioned on a topographical map with a scale of 1:25000 using actual land-use maps, forest management plan, and GIS technology, and divided into three size groups: 0-5 ha, 5-15 ha, and >15 ha. To minimize the edge effect, 20-m long transects were placed across the openings at least 25 m apart from the forest edge.

Soil samples were collected at 0-20 cm soil depth along the transects. The number of soil samples collected in each gap varied depending on its size. For gaps smaller than 2.1 ha, samples were collected every 4 m along a single transect, while for gaps larger 2.1 ha two transects were established and five soil samples taken for each. A total of 120 soil samples were collected from the 0-5 ha gaps, 90 samples from the 5-15 ha gaps and 70 samples from the >15 ha gaps.

Soil EC values were significantly affected by the size of forest openings ($P < 0.001$), with mean values of 209, 163, and 154 $\mu$hos cm$^{-1}$ for the gaps of 0-5 ha, 5-15 ha, and >15 ha, respectively. Soils of the latter
had a significant effect on all cations investigated (P < 0.05), revealing a similar trend for all cations with respect to the gap size. When the surrounding forest types were compared, soils in the gaps located within the mixed forest showed greater K⁺, Na⁺, Ca²⁺ and Mg²⁺ concentrations than soils in the gaps within the beech forest.

K⁺ concentration increased significantly as the gap size increases, from 83.88 mg L⁻¹ in the 0-5 ha gap to 134.64 mg L⁻¹ in the >15 ha. Furthermore, the average K⁺ concentrations in the soil showed significant differences between the surrounding forest types, being 85.69 mg L⁻¹ in gaps surrounded by beech forest and 115.29 mg L⁻¹ in gaps surrounded by mixed forest. In contrast to K⁺, Na⁺ concentration decreased significantly as forest gap size increased (P<0.001), averaging 22.72, 18.85 and 19.57 mg L⁻¹ for soils in the 0-5 ha, 5-15 ha, and >15 ha gaps, respectively. Soils in the 5-15 ha and >15 ha gaps had similar and significantly lower Na⁺ values than soils in the 0-5 ha gap. Moreover, surrounding forest vegetation types also significantly affected soil Na⁺ concentration in the gaps (P = 0.004). The opening surrounded by mixed forest had a mean Na⁺ value of 21.08 mg L⁻¹, whereas those surrounded by beech forest had an average of 19.66 mg L⁻¹. Significant interaction was found between the surrounding forest vegetation type and the gap size for soil Na⁺ concentration (P < 0.001). When the gap sizes were compared based on the surrounding forest types, the soil in the >15 ha gap of the beech forest had the lowest Na⁺ concentration compared to soils in other gaps of both beech and mixed forests. Additionally, there were significant differences between the surrounding forest types for the 5-15 ha and >15 ha gap sizes, but not for the 0-5 ha (Fig. 2d). There were also no significant differences between soils in the 0-5 ha and >15 ha openings, and between soils in the 5-15 ha and >15 ha gaps in the mixed forest, as well as between soils in the 0-5 ha and 5-15 ha gaps in the beech forest (Fig. 2d).

Average Ca²⁺ concentration differed significantly according to the surrounding forest cover type (P = 0.001), averaging 695.85 and 758.89 mg L⁻¹ for soils in the beech and in the mixed forest gaps, respectively. Similarly, gap size affected soil Ca²⁺ content significantly (P = 0.003). Ca²⁺ values did not show any regular pattern as the gap size increased, averaging 771.36, 619.24 and 838.30 mg L⁻¹ in the 0-5 ha, 5-15 ha and >15 ha gaps, respectively. Soils from the >15 ha gap of mixed forests had the highest and those in the same gap size of beech forests had the lowest Ca²⁺ concentrations, with rest of the gaps (P < 0.001; Fig. 3a). When the gap size was considered along with the surrounding cover type, soils in the 0-5 ha and 5-15 ha openings in beech stands had similar but significantly greater Ca²⁺ values than soils in the >15 ha gap surrounded by the same forest cover, whereas the soils in the 5-15 ha in the mixed forest had significantly greater Ca²⁺ value than the >15 ha gap size of the same forest vegetation cover (Fig. 3a).

Mean Mg²⁺ values were 59.46, 76.21, and 123.96 mg L⁻¹ for the soils in the 0-5 ha, 5-15 ha and >15 ha gaps, respectively. Soils in the >15 ha gap of mixed forests had the highest and those in the same gap size of beech forests had the lowest Mg²⁺ concentrations, with rest of the gaps (P < 0.001; Fig. 3a). When the gap size was considered along with the surrounding cover type, soils in the 0-5 ha and 5-15 ha openings in beech stands had similar but significantly greater Mg²⁺ values than soils in the >15 ha gap surrounded by the same forest cover, whereas the soils in the 5-15 ha in the mixed forest had significantly greater Mg²⁺ value than the >15 ha gap size of the same forest vegetation cover (Fig. 3a).
15 ha and >15 ha gap sizes, respectively, and soils in the 0-5 ha and 5-15 ha gaps had similar but significantly lower Mg$^{2+}$ concentrations than soils in the >15 ha gap (P < 0.032). Mg$^{2+}$ concentration was also significantly greater in soils from the mixed forest gaps (90.38 mg L$^{-1}$) compared to soils from gaps located in beech forests (59.67 mg L$^{-1}$ - P < 0.001). Mg$^{2+}$ concentration increased significantly in mixed forest openings soils, while no relationships were found between gap size and Mg$^{2+}$ concentration for beech forest openings (Fig. 3b).

The surrounding vegetation type did not significantly affect the average N$^{3+}$ concentration in gap soils, being 0.39% for soils in beech forest gaps and 0.40% for soils in the mixed forest openings. The gap size had a significant effect on N$^{3+}$ content (P < 0.001), with mean N$^{3+}$ level of 0.43 %, 0.35 % and 0.45 % in soils from the 0-5 ha, 5-15 ha, and >15 ha openings, respectively. N$^{3+}$ concentrations in soils from mixed forest gaps were similar, while those in beech forest gaps differed significantly. The soil in the 5-15 ha openings from the beech forest had the lowest N$^{3+}$ value (Fig. 3c).

The overall mean P-PO$_{4}^{3-}$ concentration differed significantly with respect to forest gap sizes (P < 0.001). The 5-15 ha gap had the highest value (208.6 mg L$^{-1}$) followed by the 0-5 ha gap (147.42 mg L$^{-1}$) and the >15 ha gap (123.56 mg L$^{-1}$). Contrastingly, surrounding vegetation did not show any significant effect on P-PO$_{4}^{3-}$ values in the soil (155.13 vs. 163.67 mg L$^{-1}$ for beech and mixed forest gaps, respectively). Soil P-PO$_{4}^{3-}$ content in the gaps surrounded by both forest types showed a similar trend. The 5-15 ha beech forest opening had significantly greater soil P-PO$_{4}^{3-}$ content than the other two gap classes, whereas the soil in the >15 ha mixed forest gap had a lower P-PO$_{4}^{3-}$ content than soils from the other two gaps of the same forest type (P = 0.008 - Fig. 3d). Among the gaps surrounded by mixed forest, the >15 ha gap had the highest P-PO$_{4}^{3-}$ value while among the gaps surrounded by beech forest, the 5-15 ha gap had the highest P-PO$_{4}^{3-}$ value (Fig. 3d). Also, surrounding forest types did not differ significantly for the same gap size.

**Discussion**

The present study revealed that gap size and the surrounding forest canopy may affect differently the soil chemistry in forest openings. However, no regular patterns were observed for soil chemical properties with respect to gap size. Our results are not always in agreement with those of earlier studies, though similar findings for soil pH are reported by Muscolo et al. (2007) and Ritter et al. (2005). On the contrary, Muscolo et al. (2010) and Arunachalam & Arunachalam (2000) found that soil pH was slightly higher in small gaps, while Kooch et al. (2010) and Haghverdi et al. (2012) reported higher pH values for large openings as compared to medium gaps. In addition, Chunyu & Xiuhai (2007) found a positive correlation between soil pH and gap size. Since soil pH affects also the form and availability of the organic matter in the soil and its associated processes (e.g., phsyco-chemical reactions, microorganism activities, and biological growth, etc), patterns of the soil pH and OM were similar in the 0-5 ha and >15 ha forest openings. According to the literature (Alfredsson et al. 1998, Turk et al. 2008), litter decomposition from broadleaves can make soil neutral or slightly acidic, as measured in the current study. In general, temperature and moisture conditions change after gap formation (Rhoades et al. 2004, Ritter et al. 2005, Scharenbroch & Bockheim 2007), influencing the OM levels and turnover rates in the forest gaps. Although soil OM is the main source of total N$^{3+}$ and other nutrients, OM content and soil chemical parameters did not show a similar trend, except for N$^{3+}$ and EC. The 5-15 ha gaps both in the beech and mixed forests had significantly lower OM than the large gaps, as found by Muscolo et al. (2010), Haghverdi et al. (2012), and Kooch et al. (2010). At the same time, Muscolo et al. (2007) and Arunachalam & Arunachalam (2000) reported lower OM content for soils in large gaps compared to small openings. Similarly, higher N$^{3+}$ values were measured in the soil from large gaps in some studies (Kooch et al. 2010, Haghverdi et al. 2012) and from small gaps in other (Arunachalam & Arunachalam 2000, Muscolo et al. 2007, 2010). Soil P-PO$_{4}^{3-}$ concentration decreased significantly with increasing the gap size from 5-15 ha to >15 ha, in agreement with Muscolo et al. (2007). Although some stu-
dies reported that a higher solar radiation due to a larger gap size may accelerate the OM decomposition and cause an increase in the amount of soil nutrients, Arunachalam & Arunachalam (2000), Scharenbroch & Bockheim (2007), and Thieli & Perakis (2009) did not find any significant gap size effect on the physical and chemical properties of most soils examined.

In the present study, no regular patterns were detected in the concentration of soil nutrients in relation to the gap size. The larger amount of rainfall occurring in large gaps as compared to small gaps may lead to higher nutrient losses by leaching (Arunachalam & Arunachalam 2000). Thus, an increase in the opening size can potentially enhance the leaching of soil nutrients in the gaps (Bartsch 2000, Scharenbroch & Bockheim 2007, Kooch et al. 2010). Additionally, larger gaps can receive more solar energy and have higher air and soil temperatures, and lower soil moisture due to higher evaporation than smaller gaps (Muscolo et al. 2007, 2010). Under these conditions, litter decomposition and microbial activities can be limited and soil fertility and nutrient availability can decrease in the large openings (Arunachalam & Arunachalam 2000, Prescott 2002).

Conclusion
Forest management activities can influence the nutrient content and availability in the soil of forest openings. In this study, gap size and surrounding forest canopy significantly affected soil chemical properties and hence soil fertility and nutrient availability in the forest gaps. Surrounding forest cover types had a significant effect on most of the soil chemical properties studied except for soil pH, while gap size did not have a significant effect on EC and levels of N\(^+3\) and P-PO\(_4\)^\(^-3\). Surrounding forest cover types had a much more significant effect on chemical characteristics of the soil than gap size.

As expected, soils in the mixed forest gaps had greater amounts of OM and cations (except for N\(^+3\) and P-PO\(_4\)^\(^-3\)) than soils in the beech forest gaps. Since large gaps receive more solar radiation and precipitation compared to small ones, it was hypothesized that the decomposition rate could be faster and soils could be richer in cations in the >15 ha gap. In contrast to this expectation, soils in the >15 ha gap had only significantly greater K\(^+\) and Mg\(^+2\) ions than the other two gap sizes. Further studies are needed to determine the critical gap size not causing an increase in the nutrient concentration in the soil solution as a result of leaching and not limiting the decomposition rate due to great changes in the gap microclimate.
